Functions in Python

Estimated time needed: **40** minutes

Objectives

After completing this lab you will be able to:

- Understand functions and variables
- Work with functions and variables

A function is a reusable block of code which performs operations specified in the function. They let you break down tasks and allow you to reuse your code in different programs.

There are two types of functions :

- Pre-defined functions
- User defined functions

You can define functions to provide the required functionality. Here are simple rules to define a function in Python:

- Functions blocks begin def followed by the function name and parentheses ().
- There are input parameters or arguments that should be placed within these parentheses.
- You can also define parameters inside these parentheses.
- There is a body within every function that starts with a colon (:) and is indented.
- You can also place documentation before the body.
- The statement return exits a function, optionally passing back a value.

An example of a function that adds on to the parameter a prints and returns the output as b:

```
# First function example: Add 1 to a and store as b

def add(a):
    """
    add 1 to a
    """
    b = a + 1
    print(a, "if you add one", b)
    return(b)
```

The figure below illustrates the terminology:

We can obtain help about a function :

```
# Get a help on add function

help(add)
```

```
Help on function add in module __main__:

add(a)
    add 1 to a
```

We can call the function:

```
# Call the function add()

add(1)
```

```
1 if you add one 2

2
```

If we call the function with a new input we get a new result:

```
# Call the function add()

add(2)
```

```
2 if you add one 3

3
```

We can create different functions. For example, we can create a function that multiplies two numbers. The numbers will be represented by the variables a and b:

```
# Define a function for multiple two numbers

def Mult(a, b):
    c = a * b
    return(c)
    print('This is not printed')

result = Mult(12,2)
print(result)
```

```
24
```

The same function can be used for different data types. For example, we can multiply two integers:

```
# Use mult() multiply two integers

Mult(2, 3)
```

```
6
```

Note how the function terminates at the return statement, while passing back a value. This value can be further assigned to a different variable as desired.

The same function can be used for different data types. For example, we can multiply two integers:

Two Floats:

```
# Use mult() multiply two floats

Mult(10.0, 3.14)
```

```
31.400000000000002
```

We can even replicate a string by multiplying with an integer:

```
# Use mult() multiply two different type values together

Mult(2, "Michael Jackson ")
```

```
'Michael Jackson Michael Jackson '
```

The input to a function is called a formal parameter.

A variable that is declared inside a function is called a local variable. The parameter only exists within the function (i.e. the point where the function starts and stops).

A variable that is declared outside a function definition is a global variable, and its value is accessible and modifiable throughout the program. We will discuss more about global variables at the end of the lab.

```
# Function Definition

def square(a):

    # Local variable b
    b = 1
    c = a * a + b
    print(a, "if you square + 1", c)
    return(c)
```

The labels are displayed in the figure:

We can call the function with an input of 3:

```
# Initializes Global variable

x = 3
# Makes function call and return function a y
y = square(x)
y
```

```
3 if you square + 1 10
```

```
10
```

We can call the function with an input of 2 in a different manner:

```
# Directly enter a number as parameter

square(2)
```

```
2 if you square + 1 5
```

```
5
```

If there is no return statement, the function returns None. The following two functions are equivalent:

```
# Define functions, one with return value None and other without
return value

def MJ():
    print('Michael Jackson')

def MJ1():
    print('Michael Jackson')
    return(None)

# See the output

MJ()
```

```
Michael Jackson
```

```
# See the output

MJ1()
```

```
Michael Jackson
```

Printing the function after a call reveals a **None** is the default return statement:

```
# See what functions returns are

print(MJ())
print(MJ1())
```

```
Michael Jackson
None
Michael Jackson
None
```

Create a function con that concatenates two strings using the addition operation:

```
# Define the function for combining strings

def con(a, b):
    return(a + b)

# Test on the con() function

con("This ", "is")
```

```
'This is'
```

```
<div class="alert alert-success alertsuccess" style="margin-top:
20px">
    <h4> [Tip] How do I learn more about the pre-defined functions in
Python? </h4>
    <p>We will be introducing a variety of pre-defined functions to
you as you learn more about Python. There are just too many functions,
so there's no way we can teach them all in one sitting. But if you'd
like to take a quick peek, here's a short reference card for some of
the commonly-used pre-defined functions: <a href="https://cf-courses-
data.s3.us.cloud-object-storage.appdomain.cloud/
IBMDeveloperSkillsNetwork-PY0101EN-SkillsNetwork/labs/Module%203/
Python_reference_sheet.pdf?
utm_medium=Exinfluencer&utm_source=Exinfluencer&utm_content=000026UJ&u
tm_term=10006555&utm_id=NA-SkillsNetwork-Channel-
SkillsNetworkCoursesIBMDeveloperSkillsNetworkPY0101ENSkillsNetwork1948
7395-2022-01-01">Reference</a></p>
</div>
```

Consider the two lines of code in Block 1 and Block 2: the procedure for each block is identical. The only thing that is different is the variable names and values.

```
# a and b calculation block1

a1 = 4
b1 = 5
c1 = a1 + b1 + 2 * a1 * b1 - 1
if(c1 < 0):
```

```
    c1 = 0
else:
    c1 = 5
c1
```

```
5
```

```
# a and b calculation block2

a2 = 0
b2 = 0
c2 = a2 + b2 + 2 * a2 * b2 - 1
if(c2 < 0):
    c2 = 0
else:
    c2 = 5
c2
```

```
0
```

We can replace the lines of code with a function. A function combines many instructions into a single line of code. Once a function is defined, it can be used repeatedly. You can invoke the same function many times in your program. You can save your function and use it in another program or use someone else's function. The lines of code in code Block 1 and code Block 2 can be replaced by the following function:

```
# Make a Function for the calculation above

def Equation(a,b):
    c = a + b + 2 * a * b - 1
    if(c < 0):
        c = 0
    else:
        c = 5
    return(c)
```

This function takes two inputs, a and b, then applies several operations to return c. We simply define the function, replace the instructions with the function, and input the new values of a1, b1 and a2, b2 as inputs. The entire process is demonstrated in the figure:

Code **Blocks 1** and **Block 2** can now be replaced with code **Block 3** and code **Block 4**.

```
a1 = 4
b1 = 5
c1 = Equation(a1, b1)
c1
```

```
5
```

```
a2 = 0
b2 = 0
c2 = Equation(a2, b2)
c2
```

```
0
```

There are many pre-defined functions in Python, so let's start with the simple ones.

The print() function:

```
# Build-in function print()

album_ratings = [10.0, 8.5, 9.5, 7.0, 7.0, 9.5, 9.0, 9.5]
print(album_ratings)
```

```
[10.0, 8.5, 9.5, 7.0, 7.0, 9.5, 9.0, 9.5]
```

The sum() function adds all the elements in a list or tuple:

```
# Use sum() to add every element in a list or tuple together

sum(album_ratings)
```

```
70.0
```

The len() function returns the length of a list or tuple:

```
# Show the length of the list or tuple

len(album_ratings)
```

```
8
```

In Python, an in-built function is a pre-defined function that is always available for use, providing common functionality without requiring any imports.

```
#You will see below will return an error as integer alone is not
considered while using a function.It either has to be in the form of
tuple, list or a set.

sum(1,2)
```

```
---------------------------------------------------------------------
-----
TypeError                                 Traceback (most recent call
last)
Cell In[26], line 3
      1 #You will see below will return an error as integer alone is
not considered while using a function.It either has to be in the form
```

```
of tuple, list or a set.
----> 3 sum(1,2)

TypeError: 'int' object is not iterable
```

```
# Define a tuple
a = (1, 2)

# Pass the tuple to the sum function and store the result in a
variable
c = sum(a)

# Print the result
print(f"The sum of the elements in the tuple {a} is {c}.")
```

```
The sum of the elements in the tuple (1, 2) is 3.
```

```
# Define a list
a = [1, 2]

# Pass the list to the sum function and store the result in a variable
c = sum(a)

# Print the result
print(f"The sum of the elements in the list {a} is {c}.")
```

```
The sum of the elements in the list [1, 2] is 3.
```

The return() function is particularly useful if you have any IF statements in the function, when you want your output to be dependent on some condition:

```
# Function example

def type_of_album(artist, album, year_released):

    print(artist, album, year_released)
    if year_released > 1980:
        return "Modern"
    else:
        return "Oldie"

x = type_of_album("Michael Jackson", "Thriller", 1980)
print(x)
```

```
Michael Jackson Thriller 1980
Oldie
```

We can use a loop in a function. For example, we can print out each element in a list:

```
# Print the list using for loop

def PrintList(the_list):
    for element in the_list:
        print(element)

# Implement the printlist function

PrintList(['1', 1, 'the man', "abc"])
```

```
1
1
the man
abc
```

The relational operators compare the Unicode values of the characters of the strings from the zeroth index till the end of the string. It then returns a boolean value according to the operator used.

```
#Compare Two Strings Directly using in operator
# add string
string= "Michael Jackson is the best"

# Define a funtion
def check_string(text):

# Use if else statement and 'in' operatore to compare the string
    if text in string:
        return 'String matched'
    else:
        return 'String not matched'

check_string("Michael Jackson is the best")
```

```
'String matched'
```

This program uses a user-defined function named compareStrings() to compare two strings.

This function receives both strings as its argument and returns 1 if both strings are equal using == operator

```
#Compare two strings using == operator and function
def compareStrings(x, y):
# Use if else statement to compare x and y
    if x==y:
        return 1

# Declare two different variables as string1 and string2 and pass
string in it
string1 = "Michael Jackson is the best"
```

```
string2 = "Michael Jackson is the best"

# Declare a variable to store result after comparing both the strings
check = compareStrings(string1, string2)

#Use if else statement to compare the string
if check==1:
    print("\nString Matched")
else:
    print("\nString not Matched")
```

```
String Matched
```

Count the Frequency of Words Appearing in a String Using a Dictionary.

Find the count of occurence of any word in our string using python. This is what we are going to do in this section, count the number of word in a given string and print it.

Lets suppose we have a 'string' and the 'word' and we need to find the count of occurence of this word in our string using python. This is what we are going to do in this section, count the number of word in a given string and print it.

The first thing, we will do is define a function and and then create a list that will be empty initially.

Next, we will add a code to convert the string to a list. Python string has a split() method. It takes a string and some separator to return a list.

Now we will declare an empty dictionary.

Next we will add code using for loop to iterate the words and value will will count the frequency of each words in the string and store them to the dictionary.

Finally we will print the dictionary.

```
# Python Program to Count words in a String using Dictionary
def freq(string):

    #step1: A list variable is declared and initialized to an empty
list.
    words = []

    #step2: Break the string into list of words
    words = string.split() # or string.lower().split()

    #step3: Declare a dictionary
    Dict = {}

    #step4: Use for loop to iterate words and values to the dictionary
    for key in words:
```

```
        Dict[key] = words.count(key)

    #step5: Print the dictionary
    print("The Frequency of words is:",Dict)

#step6: Call function and pass string in it
freq("Mary had a little lamb Little lamb, little lamb Mary had a
little lamb.Its fleece was white as snow And everywhere that Mary went
Mary went, Mary went \
Everywhere that Mary went The lamb was sure to go")
```

```
The Frequency of words is: {'Mary': 6, 'had': 2, 'a': 2, 'little': 3,
'lamb': 3, 'Little': 1, 'lamb,': 1, 'lamb.Its': 1, 'fleece': 1, 'was':
2, 'white': 1, 'as': 1, 'snow': 1, 'And': 1, 'everywhere': 1, 'that':
2, 'went': 3, 'went,': 1, 'Everywhere': 1, 'The': 1, 'sure': 1, 'to':
1, 'go': 1}
```

You can set a default value for arguments in your function. For example, in the isGoodRating() function, what if we wanted to create a threshold for what we consider to be a good rating? Perhaps by default, we should have a default rating of 4:

```
# Example for setting param with default value

def isGoodRating(rating=4):
    if(rating < 7):
        print("this album sucks it's rating is",rating)

    else:
        print("this album is good its rating is",rating)

# Test the value with default value and with input

isGoodRating()
isGoodRating(10)
```

```
this album sucks it's rating is 4
this album is good its rating is 10
```

So far, we've been creating variables within functions, but we have not discussed variables outside the function. These are called global variables. Let's try to see what printer1 returns:

```
# Example of global variable

artist = "Michael Jackson"
def printer1(artist):
    internal_var1 = artist
    print(artist, "is an artist")

printer1(artist)
```

```
# try runningthe following code
#printer1(internal_var1)
```

```
Michael Jackson is an artist
```

We got a Name Error: name 'internal_var' is not defined. Why?

It's because all the variables we create in the function is a local variable, meaning that the variable assignment does not persist outside the function.

But there is a way to create global variables from within a function as follows:

```
artist = "Michael Jackson"

def printer(artist):
    global internal_var
    internal_var= "Whitney Houston"
    print(artist,"is an artist")

printer(artist)
printer(internal_var)
```

```
Michael Jackson is an artist
Whitney Houston is an artist
```

The scope of a variable is the part of that program where that variable is accessible. Variables that are declared outside of all function definitions, such as the myFavouriteBand variable in the code shown here, are accessible from anywhere within the program. As a result, such variables are said to have global scope, and are known as global variables. myFavouriteBand is a global variable, so it is accessible from within the getBandRating function, and we can use it to determine a band's rating. We can also use it outside of the function, such as when we pass it to the print function to display it:

```
# Example of global variable

myFavouriteBand = "AC/DC"

def getBandRating(bandname):
    if bandname == myFavouriteBand:
        return 10.0
    else:
        return 0.0

print("AC/DC's rating is:", getBandRating("AC/DC"))
print("Deep Purple's rating is:",getBandRating("Deep Purple"))
print("My favourite band is:", myFavouriteBand)
```

```
AC/DC's rating is: 10.0
Deep Purple's rating is: 0.0
My favourite band is: AC/DC
```

Take a look at this modified version of our code. Now the myFavouriteBand variable is defined within the getBandRating function. A variable that is defined within a function is said to be a local variable of that function. That means that it is only accessible from within the function in which it is defined. Our getBandRating function will still work, because myFavouriteBand is still defined within the function. However, we can no longer print myFavouriteBand outside our function, because it is a local variable of our getBandRating function; it is only defined within the getBandRating function:

```
# Deleting the variable "myFavouriteBand" from the previous example to
demonstrate an example of a local variable

del myFavouriteBand

# Example of local variable

def getBandRating(bandname):
    myFavouriteBand = "AC/DC"
    if bandname == myFavouriteBand:
        return 10.0
    else:
        return 0.0

print("AC/DC's rating is: ", getBandRating("AC/DC"))
print("Deep Purple's rating is: ", getBandRating("Deep Purple"))
print("My favourite band is", myFavouriteBand)
```

```
AC/DC's rating is:  10.0
Deep Purple's rating is:  0.0

---------------------------------------------------------------------------
-----
NameError                                 Traceback (most recent call
last)
Cell In[40], line 16
     14 print("AC/DC's rating is: ", getBandRating("AC/DC"))
     15 print("Deep Purple's rating is: ", getBandRating("Deep
Purple"))
---> 16 print("My favourite band is", myFavouriteBand)

NameError: name 'myFavouriteBand' is not defined
```

Finally, take a look at this example. We now have two myFavouriteBand variable definitions. The first one of these has a global scope, and the second of them is a local variable within the getBandRating function. Within the getBandRating function, the local variable takes precedence. **Deep Purple** will receive a rating of 10.0 when passed to the getBandRating function. However, outside of the getBandRating function, the getBandRating s local variable is not defined, so the myFavouriteBand variable we print is the global variable, which has a value of **AC/DC**:

```
# Example of global variable and local variable with the same name
```

```
myFavouriteBand = "AC/DC"

def getBandRating(bandname):
    myFavouriteBand = "Deep Purple"
    if bandname == myFavouriteBand:
        return 10.0
    else:
        return 0.0

print("AC/DC's rating is:",getBandRating("AC/DC"))
print("Deep Purple's rating is: ",getBandRating("Deep Purple"))
print("My favourite band is:",myFavouriteBand)
```

```
AC/DC's rating is: 0.0
Deep Purple's rating is:  10.0
My favourite band is: AC/DC
```

When the number of arguments are unknown for a function, They can all be packed into a tuple as shown:

```
def printAll(*args): # All the arguments are 'packed' into args which
can be treated like a tuple
    print("No of arguments:", len(args))
    for argument in args:
        print(argument)
#printAll with 3 arguments
printAll('Horsefeather','Adonis','Bone')
#printAll with 4 arguments
printAll('Sidecar','Long Island','Mudslide','Carriage')
```

```
No of arguments: 3
Horsefeather
Adonis
Bone
No of arguments: 4
Sidecar
Long Island
Mudslide
Carriage
```

Similarly, The arguments can also be packed into a dictionary as shown:

```
def printDictionary(**args):
    for key in args:
        print(key + " : " + args[key])

printDictionary(Country='Canada',Province='Ontario',City='Toronto')
```

```
Country : Canada
Province : Ontario
City : Toronto
```

Functions can be incredibly powerful and versatile. They can accept (and return) data types, objects and even other functions as arguements. Consider the example below:

```
def addItems(list):
    list.append("Three")
    list.append("Four")

myList = ["One","Two"]

addItems(myList)

myList

['One', 'Two', 'Three', 'Four']
```

Note how the changes made to the list are not limited to the functions scope. This occurs as it is the lists **reference** that is passed to the function - Any changes made are on the orignal instance of the list. Therefore, one should be cautious when passing mutable objects into functions.

Come up with a function that divides the first input by the second input:

```
# Write your code below and press Shift+Enter to execute
def div(a, b):
    return(a/b)
```

Use the function con for the following question.

```
# Use the con function for the following question

def con(a, b):
    return(a + b)
```

Can the con function we defined before be used to add two integers or strings?

```
# Write your code below and press Shift+Enter to execute
Yes, for example:
con(2, 2)

  Cell In[47], line 2
    Yes, for example:
         ^
SyntaxError: invalid syntax
```

Can the con function we defined before be used to concatenate lists or tuples?

```
# Write your code below and press Shift+Enter to execute
Yes, for example:
con(['a', 1], ['b', 1])
```

```
  Cell In[48], line 2
    Yes, for example:
         ^
SyntaxError: invalid syntax
```

Write a function code to find total count of word `little` in the given string: `"Mary had a little lamb Little lamb, little lamb Mary had a little lamb.Its fleece was white as snow And everywhere that Mary went Mary went, Mary went Everywhere that Mary went The lamb was sure to go"**`

```
# Write your code below and press Shift+Enter to execute
# Python Program to Count words in a String using Dictionary
def freq(string,passedkey):

    #step1: A list variable is declared and initialized to an empty
list.
    words = []

    #step2: Break the string into list of words
    words = string.split() # or string.lower().split()

    #step3: Declare a dictionary
    Dict = {}

    #step4: Use for loop to iterate words and values to the dictionary
    for key in words:
        if(key == passedkey):
            Dict[key] = words.count(key)
    #step5: Print the dictionary
    print("Total Count:",Dict)

#step6: Call function and pass string in it
freq("Mary had a little lamb Little lamb, little lamb Mary had a
little lamb.Its fleece was white as snow And everywhere that Mary went
Mary went, Mary went \
Everywhere that Mary went The lamb was sure to go","little")
```

```
Total Count: {'little': 3}
```

Congratulations, you have completed your first lesson and hands-on lab in Python.
